## CaM Kinase Kinase $\beta$ -Mediated Activation of the Growth Regulatory Kinase AMPK Is Required for Androgen-Dependent Migration of Prostate Cancer Cells

Daniel E. Frigo<sup>1</sup>, Matthew K. Howe<sup>1</sup>, Bryan M. Wittmann<sup>1</sup>, Abigail M. Brunner<sup>1</sup>, Ian Cushman<sup>1</sup>, Qianben Wang<sup>2</sup>, Myles Brown<sup>3</sup>, Anthony R. Means<sup>1</sup>, and Donald P. McDonnell<sup>1</sup>

### Abstract

While patients with advanced prostate cancer initially respond favorably to androgen ablation therapy, most experience a relapse of the disease within 1–2 years. Although hormone-refractory disease is unresponsive to androgen-deprivation, androgen receptor (AR)-regulated signaling pathways remain active and are necessary for cancer progression. Thus, both AR itself and the processes downstream of the receptor remain viable targets for therapeutic intervention. Microarray analysis of multiple clinical cohorts showed that the serine/threonine kinase *Ca<sup>2+</sup>/calmodulin-dependent protein kinase kinase  $\beta$*  (*CaMKK $\beta$* ) is both highly expressed in the prostate and further elevated in prostate cancers. Using cellular models of prostate cancer, we have determined that androgens (a) directly increase the expression of a *CaMKK $\beta$*  splice variant and (b) increase functional *CaMKK $\beta$*  protein levels as determined by the phosphorylation of both *CaMKI* and AMP-activated protein kinase (AMPK), two of *CaMKK $\beta$* 's primary substrates. Importantly, inhibition of the *CaMKK $\beta$* -AMPK, but not *CaMKI*, signaling axis in prostate cancer cells by pharmacological inhibitors or siRNA-mediated knockdown blocks androgen-mediated migration and invasion. Conversely, overexpression of *CaMKK $\beta$*  alone leads to both increased AMPK phosphorylation and cell migration. Given the key roles of *CaMKK $\beta$*  and AMPK in the biology of prostate cancer cells, we propose that these enzymes are potential therapeutic targets in prostate cancer. *Cancer Res*; 71(2); 528–37. ©2010 AACR.

### Introduction

Prostate cancer is the most common malignancy in men and is second only to lung cancer in terms of cancer mortalities (1). If diagnosed early, most localized prostate tumors are successfully treated by surgery alone. However, as with many cancers, the treatment of the advanced disease state requires a systemic approach to inhibit the growth and spread of secondary metastases. Prostate cancers express the androgen receptor (AR) and rely on androgens for growth and

survival (2). Subsequently, androgen ablation therapies are the standard of care for late-stage disease. Although 80% of patients with prostate cancer respond favorably to initial androgen ablation therapy, most patients experience a relapse of the disease within 1–2 years (2). Despite the unresponsiveness of the hormone-refractory disease to androgen-deprivation therapy, AR-regulated signaling pathways remain active and are necessary for cancer progression (3). Consequently, AR and the processes downstream of the receptor remain viable targets for therapeutic intervention.

Several approaches are currently used to target the AR signaling axis in prostate cancer. Current therapies focus on decreasing the levels of circulating androgens and/or competitively blocking the AR transcriptional complex. Specifically, gonadotropin-releasing hormone (GnRH) agonists are used to suppress the testicular production of testosterone whereas antiandrogens, such as bicalutamide, function by competitively inhibiting the interaction of androgens with AR. The initial response to either form of androgen deprivation is very high. However, the rapid onset of resistance to these interventions has highlighted the need for novel strategies to target the hormone-independent activities of AR. In this regard, our group and others have shown that the targeting of specific signaling pathways downstream of AR represents a potential new modality for the treatment of prostate cancer (4–7).

Most of the studies on the role of androgens in prostate cancer have focused on defining the mechanisms underlying

the mitotic actions of this hormone (8). However, there is a growing body of evidence that AR signaling also influences tumor cell migration and invasion. Of note, different clinical trials of goserelin (a GnRH analog) in prostate cancer patients show reduced incidences of distant metastases (9, 10). Furthermore, it has recently been reported that MDV3100, a second-generation AR-antagonist, decreases the number of circulating tumor cells in approximately half of the treated castration-resistant patients (11). Cumulatively, these data suggest that androgen ablation therapy not only inhibits the growth of the primary tumor, but also reduces progression to metastatic disease. The onus is now on researchers to identify what specific cellular processes regulated by AR contribute to the pathogenesis of prostate cancer and ultimately, whether they represent realistic therapeutic targets.

To identify potential new points of intervention in AR-driven prostate cancer, we focused on candidate target proteins that are a) expressed in the prostate, b) regulated by AR, c) track with disease outcome, and d) likely to be druggable. We also included in our criteria the requirement that the target be expressed in various cellular models of prostate cancer. Using these criteria, the Ca<sup>2+</sup>/calmodulin-dependent protein kinase kinase  $\beta$  (CaMKK $\beta$ ) was identified as a protein of interest. Subsequently, we carried out a comprehensive analysis of its role in prostate cancer and showed that CaMKK $\beta$  is likely to be a useful target for the treatment of this disease.

## Materials and Methods

A description of the chemicals, antibodies, plasmids, and stable cell lines used in this study can be found in the Supplementary Materials.

### Cell culture and RNA

The LNCaP and VCaP human prostate carcinoma cell lines were obtained from ATCC and maintained as recommended. All experiments were carried out with cells of passage less than 25. These cells were authenticated by morphological inspection and mycoplasma testing by the ATCC. Furthermore, their response to androgens was authenticated using growth and reporter gene assays. RNA from placenta, skeletal muscle, cerebellum, whole brain, and normal prostate was from Clontech. RNA from glioblastoma cell lines was a generous gift from Valerie Curtis.

### RNA isolation, cDNA preparation, and quantitative and standard reverse transcription (RT)-PCR

RNA isolation, cDNA preparation, and quantitative RT-PCR (qPCR) were carried out as previously described using 36B4 as a control (12). Standard RT-PCR was carried out using the Advantage GC 2 Polymerase Mix and PCR Kit (Clontech). All qPCR and RT-PCR primers used in this study are listed in Supplementary Table 1.

### Western blot analysis

Western blots were conducted as previously described (12) with the exception that a modified radioimmunoprecipitation

assay (RIPA) buffer [50 mmol/L Tris (pH 8.0), 200 mmol/L NaCl, 1.5 mmol/L MgCl<sub>2</sub>, 1% Triton X-100, 1 mmol/L EGTA, 10% glycerol, 50 mmol/L NaF, 2 mmol/L Na<sub>3</sub>VO<sub>4</sub> and protease inhibitors] was used. Results shown are representative blots. For each sample, protein levels were determined by densitometry using the ImageJ software (NIH) and normalizing to the indicated controls.

### Small interfering RNA (siRNA) transfection of human prostate cells

Stealth siRNA (Invitrogen) transfections were carried out as previously described (5). The sequences of all siRNAs used in this study are listed in Supplementary Table 1.

### Chromatin immunoprecipitation

Chromatin immunoprecipitation (ChIP) was conducted as previously described (4). All primers used for ChIP qPCR analysis are listed in Supplementary Table 1.

### Transient transfections and reporter gene assays

Transient transfections and reporter gene assays were carried out as previously described (4).

### Cell proliferation assay

Proliferation assays were carried out as previously described (12) by measuring the cellular DNA content using the FluoReporter Blue Fluorometric double-stranded DNA Quantitation Kit (Invitrogen) as per the manufacturer's protocol.

### Migration and invasion assays

Boyden dual-chamber migration assays were carried out as previously described (4). Invasion assays were carried out the same as migration assays except that inserts were layered with 100  $\mu$ L of Matrigel extracellular matrix (BD Biosciences) prior to reseeding of cells.

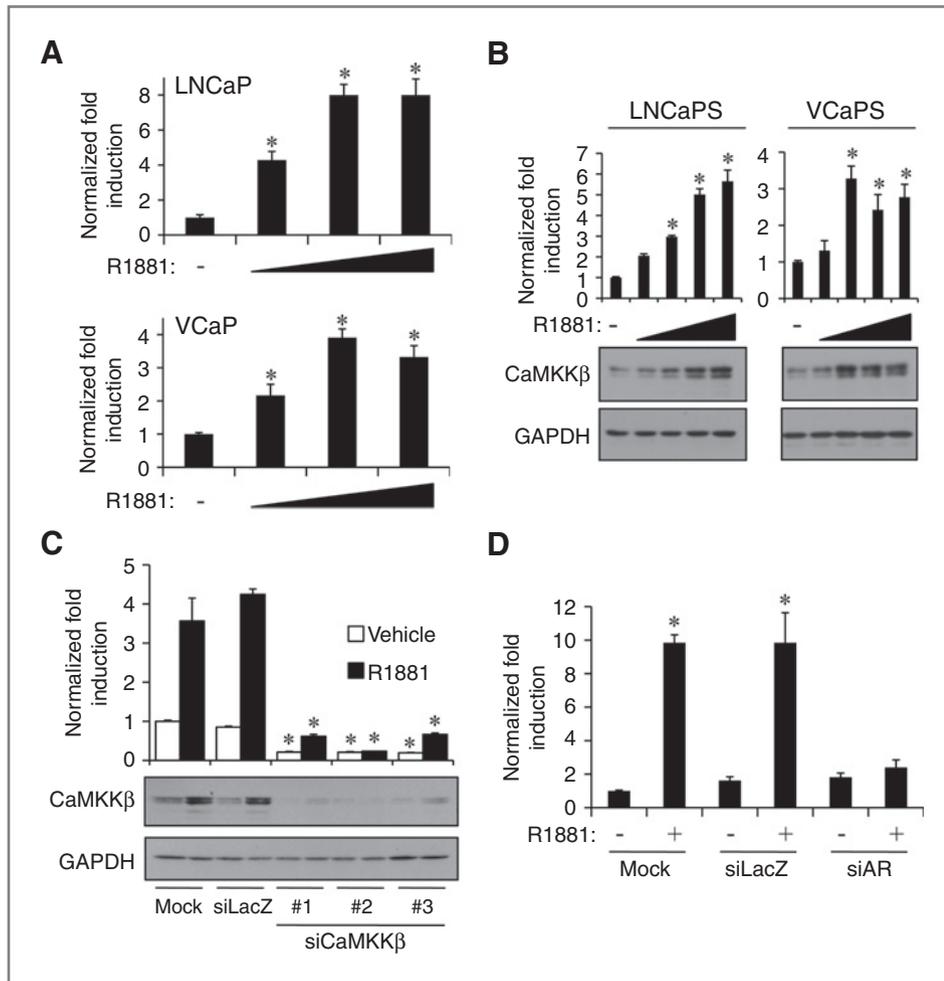

### Statistical analysis

Data were analyzed using 1-way ANOVA and *post hoc* Dunnett's test with GraphPad Prism, Version 4 (GraphPad Software, Inc.). Unless otherwise noted, significance was determined at the  $P < 0.05$  level.

## Results

### Androgens increase CaMKK $\beta$ mRNA and protein levels in an AR-dependent manner

In an effort to identify novel prostate cancer therapeutics, we have focused on defining key regulators downstream of AR action that contribute to prostate pathobiology and that may be amenable to pharmacological exploitation. As a first step in this process, we analyzed the expression level of mRNAs encoding targetable signaling molecules using microarray data derived from androgen-treated LNCaP prostate cancer cells (13). These studies suggested that one such candidate, CaMKK $\beta$ , was upregulated by androgens. To confirm the significance of this observation, CaMKK $\beta$  mRNA levels were analyzed by qPCR following treatment with the synthetic

**Figure 1.** Androgens increase CaMKK $\beta$  levels in an AR-dependent manner. LNCaP or VCaP cells were treated for 24 hours with vehicle or increasing concentrations of the synthetic androgen R1881 (A-0.01, 1, and 10 nmol/L; B-0.01, 0.1, 1, and 10 nmol/L). A, after treatment, cells were lysed, and RNA was isolated and reverse transcribed. The expression of CaMKK $\beta$  was assessed using qPCR. B, after treatment, cells were subjected to Western blot analysis and subsequent densitometry (top). CaMKK $\beta$  protein levels were normalized to GAPDH loading control. A and B, results are expressed as fold induction over vehicle-treated cells  $\pm$  SE ( $n = 3$ ). \*, significant changes from vehicle-treated cells. C, LNCaP cells were transiently transfected with mock or Stealth siRNAs targeting a negative control (siLacZ) or CaMKK $\beta$  (#1–3). Two days later, cells were treated for 24 hours  $\pm$  10 nmol/L R1881. Whole-cell extracts were subjected to Western blot analysis and densitometry (top) as described in B. \*, significant changes from mock-transfected cells. D, LNCaP cells were transfected as described in C with mock or Stealth siRNAs targeting LacZ or AR and treated for 24 hours. The expression of CaMKK $\beta$  was assessed as in A using qPCR.

androgen R1881. In both LNCaP and VCaP prostate cancer cell lines, CaMKK $\beta$  mRNA levels increased in a dose-dependent manner (Fig. 1A). Furthermore, western immunoblot analysis revealed a corresponding dose-dependent increase in CaMKK $\beta$  protein levels in both cell lines (Fig. 1B). The specificity of the antibodies used in this study was verified using 3 different siRNAs targeting CaMKK $\beta$  mRNA (Fig. 1C). In addition, analogous immunoblot results were obtained using a second antibody (clone 1A11) directed against CaMKK $\beta$  (Supplementary Fig. S1). Finally, androgen-mediated induction, but not the basal expression, of CaMKK $\beta$  mRNA was abrogated in cells in which AR expression was inhibited using a validated siRNA (4) directed against the AR mRNA (Fig. 1D). Taken together, these data show that androgens, acting through AR, increase both CaMKK $\beta$  mRNA and protein levels in multiple cellular models of prostate cancer.

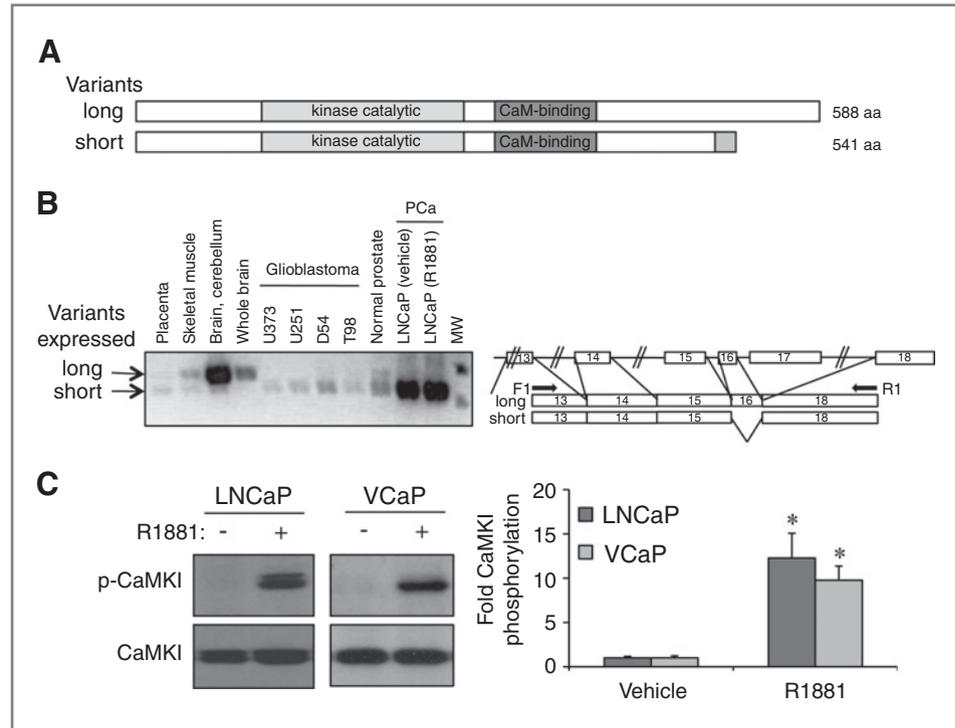

#### Functionally active splice variants of CaMKK $\beta$ are expressed in response to androgens in the prostate

Given that AR increases CaMKK $\beta$  levels in multiple cellular models of prostate cancer, we next determined if its expression correlated with the development of prostate cancer in

human samples. Analysis of the clinically annotated prostate cancer data sets accessible through Oncomine revealed that *CaMKK $\beta$*  expression increases with grade (14–17) (Supplementary Figs. S2A and B). Interestingly, this analysis also revealed that *CaMKK $\beta$*  was consistently overexpressed in prostate tumors, but not other malignancies (Supplementary Fig. S2C) (18). Importantly, approximately 80% of metastatic prostate cancers from noncastrated patients overexpress *CaMKK $\beta$* , whereas fewer than 15% of castrated patients show elevated levels of CaMKK $\beta$ , indicating AR regulation of CaMKK $\beta$  in an *in vivo* clinical setting (19).

The full-length CaMKK $\beta$  protein is encoded by an mRNA composed of 18 exons. Interestingly, the majority of commercially available CaMKK $\beta$  antibodies target the C-terminus of the protein that is absent in some functionally active splice variants (20). Thus, given that the expression of CaMKK $\beta$  in the prostate has not been reported previously, we hypothesized that the prostate, and prostate cancers, may express a functionally important splice variant(s) of CaMKK $\beta$  that was not recognized by the most commonly used antibodies. To test this hypothesis, we carried out RT-PCR analysis using primers spanning various exon boundaries to examine the splice variant repertoire in the

**Figure 2.** The prostate expresses a different functional splice variant of CaMKK $\beta$  compared with brain. A, schematic of CaMKK $\beta$  splice variants. B, RT-PCR using primers spanning specific exons (indicated in right schematic) was conducted on cDNA generated from various tissues and cell lines. C, LNCaP or VCaP cells were treated for 24 hours  $\pm$ 10 nmol/L R1881. Cell lysates were then subjected to Western blot analysis and subsequent densitometry (right). Phospho-CaMKI (p-CaMKI) protein levels were normalized to total CaMKI. Results are expressed as fold CaMKI phosphorylation over vehicle-treated cells  $\pm$  SE ( $n = 3$ ). \*, significant changes from vehicle-treated cells.

normal prostate and in prostate cancer cells. In this manner, it was shown that unlike in brain, which expresses a longer variant, both normal prostate and prostate cancer cells predominantly express shorter variants of CaMKK $\beta$  (Figs. 2A and B and Supplementary Fig. S3). The variants found are equivalent to the previously described CaMKK $\beta$  splice variants 2 and 7 that lack exon 16 (of note, splice variants 2 and 7 make identical protein products) (20). Interestingly, these shorter variants were also found in brain tumors (Fig. 2B). A complete analysis of the additional variants expressed in the prostate/prostate cancer is described in Supplementary Figure S3. Importantly, phosphorylation of the classical CaMKK $\beta$  target CaMKI was observed in both androgen-treated LNCaP and VCaP cells (Fig. 2C), indicating that the CaMKK $\beta$  variant expressed in prostate cancer cells is functionally active.

### CaMKK $\beta$ is necessary and sufficient for AR-mediated prostate cancer cell migration and invasion

Given that the expression of CaMKK $\beta$  is upregulated by androgens and is elevated in prostate cancer, we next wanted to assess its potential role(s) in processes of pathological importance in this disease. As a first step, we evaluated the ability of the CaMKK antagonist STO-609 to inhibit the androgen-mediated cellular growth of prostate cancer cells. However, at a concentration that suppressed CaMKK $\beta$  activity (Supplementary Fig. S4A), this drug had no significant effect on LNCaP and VCaP cell number over the 7-day period of this assay (Fig. 3A and Supplementary Fig. S4B).

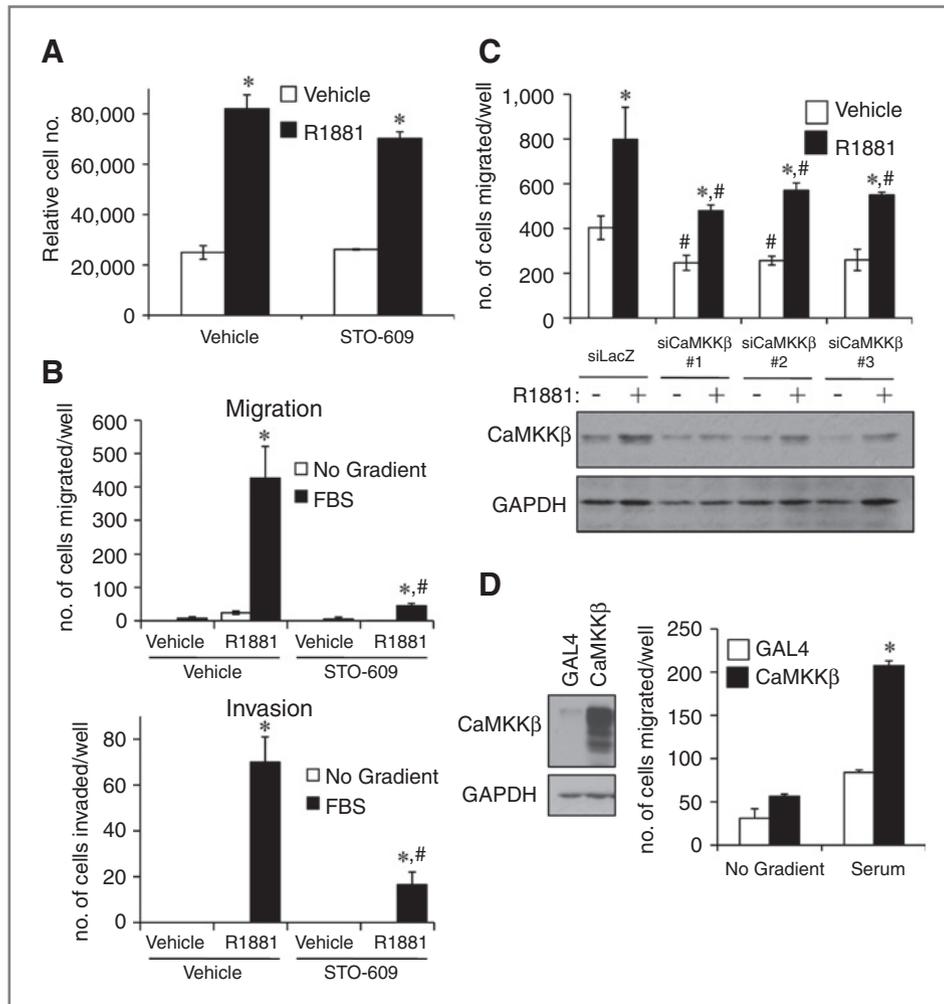

In addition to proliferation, androgens increase the migration of prostate cancer cells (4, 21). Since CaMKK $\beta$  has recently been implicated in cell migration during neuronal

development (22, 23), we next asked whether CaMKK $\beta$  is important for AR-mediated prostate cancer cell migration and/or invasion. Using Boyden dual-chamber migration assays, treatment with the CaMKK antagonist STO-609 blocked the androgen-mediated migration of both LNCaP (Fig. 3B, top) and VCaP prostate cancer cells (Supplementary Fig. S4C). Importantly, STO-609 also inhibited androgen-mediated invasion of LNCaP cells through a Matrigel extracellular matrix (Fig. 3B, bottom). Furthermore, knockdown of CaMKK $\beta$  suppressed, whereas its overexpression increased, both basal and androgen-stimulated cell migration (Figs. 3C, 3D and Supplementary Figs. S4D, S4E). These findings highlight a heretofore unrecognized role for CaMKK $\beta$  in prostate cancer cell migration and invasion.

### Definition of the molecular mechanism for AR-mediated CaMKK $\beta$ mRNA expression

Using a knockdown/replacement strategy, it was shown that expression of wild-type AR, but not a transcriptionally inactive DNA binding mutant (C562S), was able to complement the knockdown of endogenously expressed AR in an LNCaP cell migration assay (Supplementary Fig. S5). Furthermore, at a concentration that inhibits the expression of secondary androgen target genes (ex. *CXCR4* (4)), cycloheximide treatment did not block the R1881-mediated increase in CaMKK $\beta$  mRNA levels (Fig. 4A). Together, these data indicate that *CaMKK $\beta$*  is a primary AR target gene.

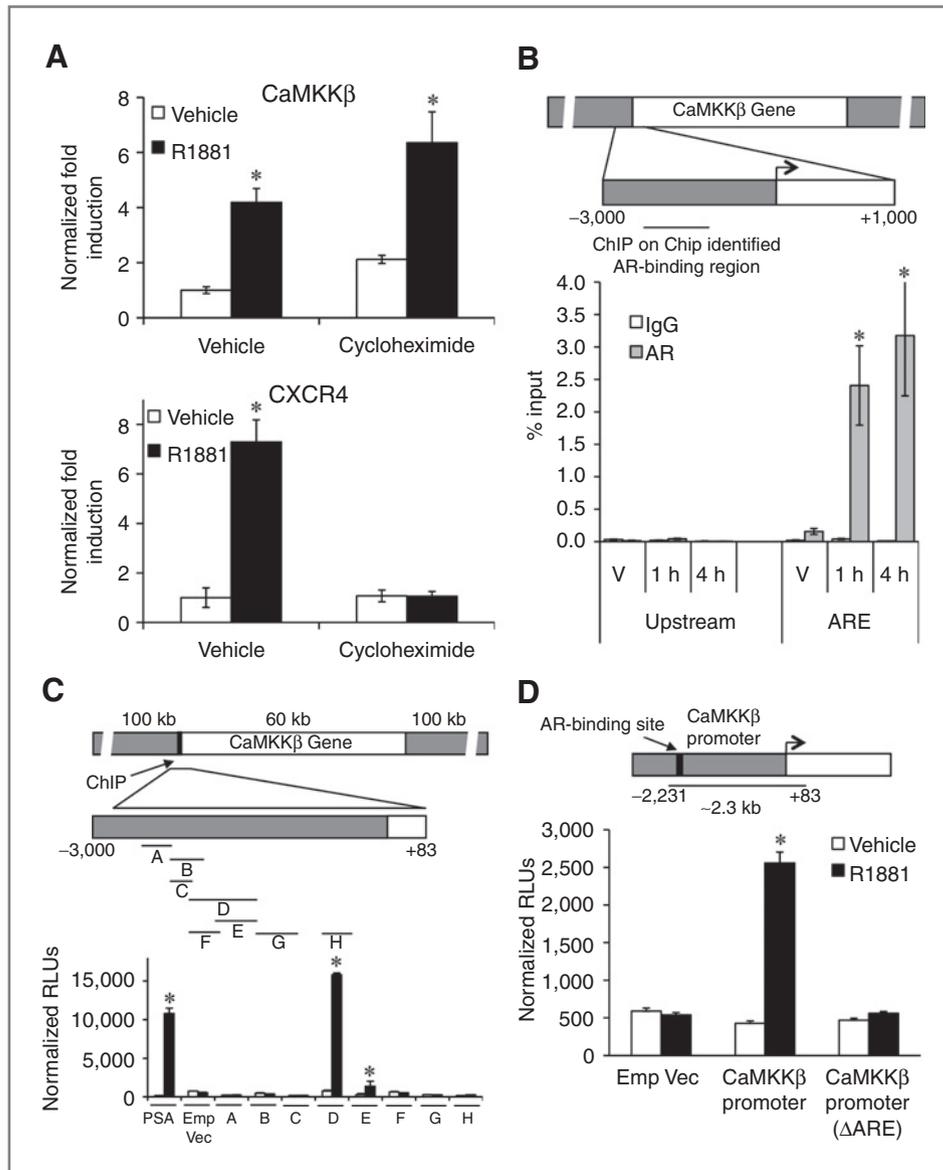

By mining our previously published ChIP on Chip data (24), we identified a putative AR binding region located approximately 2.3 kb upstream of the *CaMKK $\beta$*  transcriptional start site (Fig. 4B, top). No other AR binding was

**Figure 3.** CaMKK $\beta$  is required and sufficient for the androgen-mediated migration and invasion of prostate cancer cells. **A**, LNCaP cells were plated in 96-well plates and grown for 3 days. Cells were treated  $\pm$  1 nmol/L R1881 and  $\pm$  30  $\mu$ mol/L STO-609 on day 3, day 5, and day 7. On day 10, cells were lysed and the relative number of cells was measured with the fluorescent DNA binding dye FluoReporter Blue. Each sample was done in triplicate, and results from a representative experiment are shown. Results are expressed as relative cell number  $\pm$  SE ( $n = 2$ ). \*, significant changes from vehicle (no R1881)-treated cells. **B**, LNCaP cells were pretreated for 1 hour  $\pm$  30  $\mu$ mol/L STO-609 prior to overnight treatment  $\pm$  10 nmol/L R1881. Cells were then dissociated and reseeded into the top chamber for a Boyden migration or Matrigel extracellular matrix invasion assay. Fresh medium with the corresponding treatments was added to the top and bottom chambers whereas either no chemoattractant or 5% FBS (serum) was added to the bottom chamber. After 16 hours, migrated cells were fixed, stained, and counted in 3 different microscopic fields and added together. The results are expressed as mean  $\pm$  SE ( $n = 3$ ). \*, significant changes from vehicle (no R1881)-treated cells. #, significant changes from vehicle (no STO-609)-treated cells. **C** top, LNCaP cells were transfected with indicated siRNAs. Two days after transfection, cells were treated  $\pm$  10 nmol/L R1881 and subjected to a Boyden migration assay as described in **B**. \*, significant changes from vehicle-treated cells; #, significant changes from control (siLacZ)-transfected cells. **C** bottom, Western blot to show CaMKK $\beta$  knockdown. Quantification of these blots is presented in Supplementary Fig. S4D. **D** right, LNCaP cells stably expressing either GAL4 (control) or CaMKK $\beta$  were subjected to a migration assay as described in **B** using  $\pm$  5% FBS as chemoattractant. The results are expressed as mean  $\pm$  SE ( $n = 3$ ). \*, significant changes from LNCaP-GAL4 cells. **D** left, Western blot confirming CaMKK $\beta$  expression. Quantification of these blots is presented in Supplementary Fig. S4E.

detected within the *CaMKK $\beta$*  gene or within 100 kb in either direction of the gene. The validity of this AR-binding site was confirmed using ChIP assays, which showed that AR was recruited to this region of the promoter within 1 hour following R1881 treatment (Fig. 4B, bottom). Given these data, we focused on characterizing the functionality of the putative androgen response element (ARE) identified. To this end, we cloned overlapping regions of *CaMKK $\beta$* 's 5' upstream region and tested their ability to confer androgen

responsiveness to an enhancerless luciferase reporter gene. In this manner, we determined that a construct incorporating a fragment, -2231 to -1632 (D), and an overlapping fragment, -2019 to -1632 (E), contained an AR-dependent enhancer (Fig. 4C). Both fragments D and E exhibited androgen responsiveness in a dose-dependent manner that was suppressed by the antiandrogen Casodex (Supplementary Fig. S6A). Similar results were obtained in VCaP cells (Supplementary Fig. S6B). Deletion analysis further

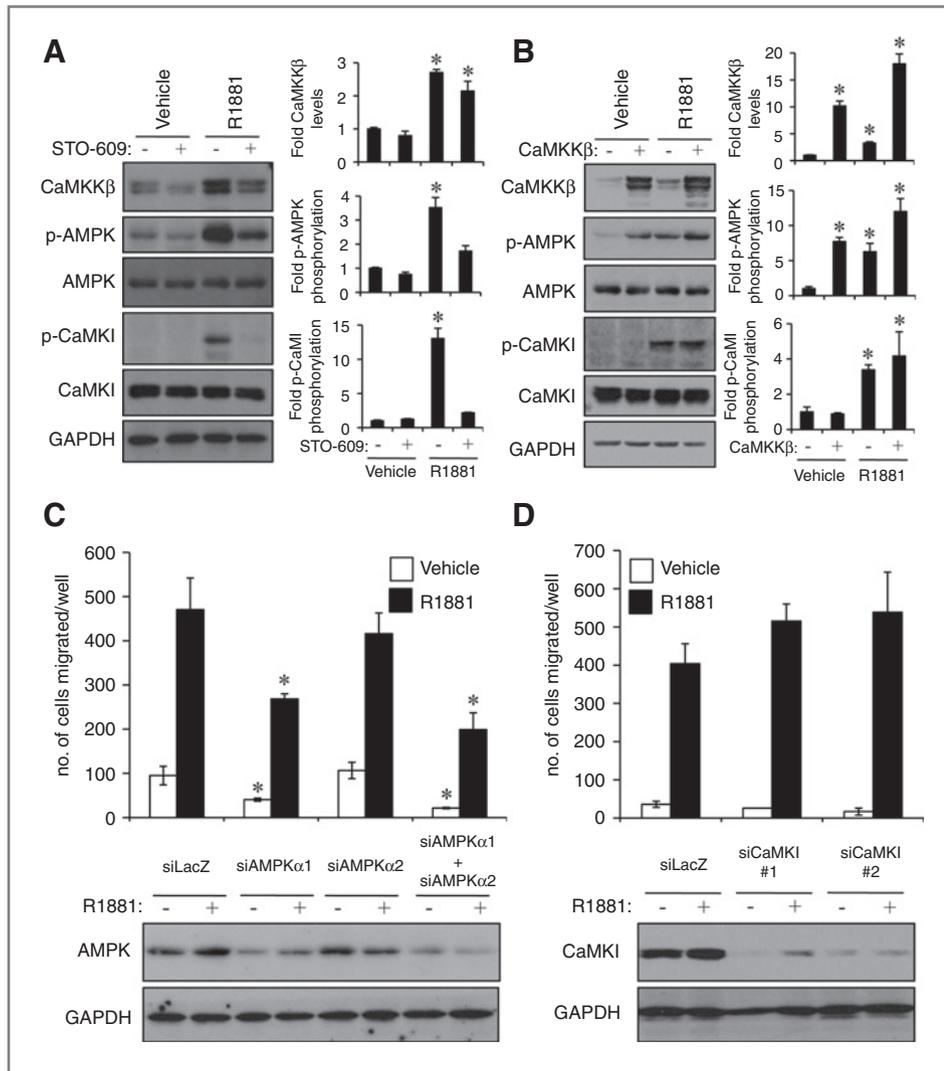

**Figure 4.** Identification of the ARE that regulates *CaMKK $\beta$*  expression. **A**, LNCaP cells were pretreated for 1 hour with vehicle or 1  $\mu$ M cycloheximide followed by vehicle or 10 nmol/L R1881 for 24 hours. *CaMKK $\beta$*  or *CXCR4* mRNA levels were quantitated using qPCR. Results are expressed as fold induction over vehicle (no R1881)-treated cells  $\pm$  SE ( $n = 3$ ). \*, significant changes from vehicle-treated cells. **B**, LNCaP cells were treated with vehicle (V) or 10 nmol/L R1881 for 1 or 4 hours. Cross-linked chromatin was immunoprecipitated with indicated antibodies. The precipitated DNA was amplified using primers spanning a region identified using ChIP on Chip data as a potential AR-binding site (indicated in top schematic) or a distal upstream region (negative control). The results are presented as percent input  $\pm$  SE ( $n = 3$ ). \*, significant changes from IgG controls. **C**, various enhancer luciferase reporter constructs (depicted in top model) were transfected into LNCaP cells and treated overnight  $\pm$  10 nmol/L R1881. After treatment, cells were harvested and assayed for luciferase activity. Luciferase values were normalized to  $\beta$ -galactosidase control. Data are the mean relative light units (RLUs)  $\pm$  SEM for one representative experiment conducted in triplicate ( $n = 3$ ). \*, significant changes from vehicle-treated cells. **D**, *CaMKK $\beta$*  promoter constructs (depicted in top model) were transfected into LNCaP cells and then treated overnight with vehicle or 10 nmol/L R1881. After treatment, cells were harvested and assayed for luciferase activity as in **C**. PSA, prostate-specific antigen. Emp Vec, empty vector.

narrowed down the androgen-responsive region to a 79 bp stretch of DNA that included a sequence, GTAACAtgaTG-TAAA that resembled the consensus androgen-response element (ARE) AGAACAnnnTGTCT (Supplementary Fig. S6C). Importantly, deletion of the 15 bp ARE in the full-length *CaMKK $\beta$*  promoter construct (-2231 to +83) completely abolished the androgen responsiveness

(Fig. 4D). Thus, in the context of prostate cancer cells, *CaMKK $\beta$*  is a direct target of AR.

#### Androgens promote prostate cancer cell migration through an AR-*CaMKK $\beta$* -AMPK signaling axis

CaMKI, CaMKIV, and more recently, AMPK have been shown to be downstream targets of *CaMKK $\beta$*  (25). Since

**Figure 5.** Androgen-mediated migration occurs through a CaMKK $\beta$ -AMPK-dependent pathway. **A**, LNCaP cells were pretreated for 1 hour  $\pm$  30  $\mu$ M STO-609 prior to overnight treatment  $\pm$  10 nmol/L R1881. Cell lysates were then subjected to Western blot analysis and subsequent densitometry (right). CaMKK $\beta$  levels were normalized to GAPDH. Phospho-CaMKI (p-CaMKI) levels were normalized to total CaMKI. Phospho-AMPK (p-AMPK) levels were normalized to total AMPK. Results are expressed as fold induction/phosphorylation over double vehicle-treated cells + SE ( $n = 3$ ). \*, significant changes from vehicle-treated cells. **B**, LNCaP cells stably expressing either GAL4 or CaMKK $\beta$  were treated overnight  $\pm$  10 nmol/L R1881. Cell lysates were then subjected to Western blot analysis and densitometry (right). Results are expressed as fold induction/phosphorylation over LNCaP-GAL4 vehicle-treated cells + SE ( $n = 3$ ). \*, significant changes from LNCaP-GAL4 vehicle-treated cells. **C** and **D**, LNCaP cells were transfected with indicated siRNAs, treated and subjected to a migration assay (top) or Western blot analysis (bottom) as in Fig. 3C. \*, significant changes from control (siLacZ)-transfected cells. Quantification of the blots is presented in Supplementary Fig. S7.

CaMKIV is not expressed in the prostate (data not shown), we tested whether AR-CaMKK $\beta$  signaling led to increased CaMKI and/or AMPK signaling. Western blot analysis revealed that androgens increased the phosphorylation of both CaMKI and AMPK at their CaMKK $\beta$  activation loop target sites (T177 and T172, respectively) in both LNCaP and VCaP cells, an effect that was reversed by pretreatment with STO-609 (Fig. 5A and Supplementary Fig. S7A). Interestingly, we found that overexpression of CaMKK $\beta$  alone was sufficient to increase the phosphorylation/activity of AMPK, but not CaMKI (Fig. 5B). These findings indicated that AMPK, rather than CaMKI, could be regulating cell migration because CaMKK $\beta$  overexpression alone was also sufficient to increase migration (Fig. 3D). To verify this, we used our most efficacious siRNAs (Supplementary Fig. S7B) to knockdown both isoforms of the catalytic subunit of AMPK (Fig. 5C, bottom and Supplementary Fig. S7C) or CaMKI (Fig. 5D, bottom and Supplementary Fig. S7D). In this manner, it was shown that loss of AMPK, but not CaMKI, resulted in decreased prostate cancer cell migra-

tion (Figs. 5C and D). Similarly, siRNA-mediated knockdown of AMPK decreased both basal and CaMKK $\beta$ -driven migration, indicating that either the residual AMPK activity left after siRNA transfection is sufficient to promote migration or an additional downstream target, unknown at this time, exists for CaMKK $\beta$  (Supplementary Fig. S8). In support of the results observed upon CaMKK $\beta$  mRNA knockdown, cotreatment of cells with the AMPK antagonist compound C, at a concentration that inhibited its kinase activity, completely abolished androgen-mediated cell migration (Supplementary Figs. S9A and B). However, in addition to inhibiting AMPK, we have determined that compound C also exhibits indirect inhibitory actions on AR-mediated transcription, a finding that makes it difficult to use the drug alone to implicate AMPK as the sole target of CaMKK $\beta$  (Supplementary Fig. S9C). Nevertheless, treatment of LNCaP cells with the AMP mimetic AICAR alone was sufficient to increase cell migration (Supplementary Figs. S9A and D). These data highlight a central role for AMPK in prostate cancer cell migration. Definition of the mechanism

(s) by which AMPK interfaces with the cellular processes responsible for migration and invasion is currently under investigation.

## Discussion

The androgen-signaling axis constitutes the primary and most successful therapeutic target in prostate cancer (26). Regardless, the mechanism(s) by which AR impacts processes of pathological importance and the signaling pathways it modulates to accomplish these activities remain largely unknown. It is of significance, therefore, that we show that the CaMKK $\beta$ -AMPK signaling pathway is downstream of AR and mediates the effects of androgens on prostate cancer cell migration and invasion. Importantly, both CaMKK $\beta$  and AMPK are druggable targets that potentially can be exploited to generate new prostate cancer therapeutics.

CaMKK $\beta$  is highly expressed in the brain, where it functions to regulate axonal outgrowth, dendritic maturation, and the formation of dendritic spines and synapses (27). These processes are regulated by the CaMKK $\beta$ -initiated phosphorylation and activation of CaMKI and CaMKIV, two of its known primary substrates. Recently, AMPK has been identified as a third substrate of CaMKK $\beta$  (28–30). AMPK coordinates energy balance, fatty acid oxidation, autophagy, and CO<sub>2</sub> sensing in both neuronal and nonneuronal tissues. It is composed of an  $\alpha$  catalytic subunit and  $\beta$  and  $\gamma$  regulatory subunits. Our data show that CaMKK $\beta$ -induced prostate cancer cell migration requires AMPK and, more specifically, the  $\alpha$ 1 catalytic kinase subunit of AMPK (Fig. 5). These findings are not completely surprising as 1) the  $\alpha$ 1 subunit, but not the  $\alpha$ 2 subunit, has a predominately cytoplasmic cellular localization and thus, would be the more likely target for the cytoplasmically localized CaMKK $\beta$  protein (31) and perhaps more importantly 2) the  $\alpha$ 2 subunit is not highly expressed in the prostate (32) or in prostate cancer cells (data not shown). Regardless, our data show an additional role for the CaMKK $\beta$ -AMPK-signaling axis in prostate cancer cell migration.

The role of AMPK in prostate cancer pathogenesis has been controversial. Studies have shown that AMPK is frequently activated in human prostate cancers and inhibition of its activity, using the antagonist compound C, has inhibitory effects on cell growth (33). Conversely, several laboratories, including our own (data not shown), have shown that AICAR and the antidiabetic drugs metformin and rosiglitazone, activators of AMPK, also inhibit prostate cancer cell growth (34–36). These discrepancies could be attributed to the pleiotropic effects of the various small molecule modulators. For example, AMPK-activators, such as AICAR, function by mimicking cellular stress and therefore, may potentiate other stress responses and activate all cellular AMPK. Hence, small molecule AMPK activators may block cell growth through a variety of indirect mechanisms. Nonetheless, it is possible that the role of AMPK as a master regulator of metabolism includes sensing cellular starvation, halting cellular growth and the subsequent induction of cell motility, thus allowing cells to migrate toward more nutrient-rich environments.

AMPK signaling has been implicated in angiogenesis and specifically in endothelial cell migration (37). At this time, however, it is unclear how AMPK controls prostate cancer cell migration. In both neuronal and endothelial cells, CaMKK $\beta$  and/or AMPK have been shown to potentiate the activity of Rac1 (23, 38, 39), a master regulator of cellular migration (40). Thus, the CaMKK $\beta$ -AMPK signaling pathway may augment prostate cell migration and invasion through activation of Rac1. Indeed, preliminary data in our laboratory suggests androgens increase Rac1 activity (data not shown). Additionally, elevated Rac1 activity has been shown to increase the aggressiveness of prostate cancer cells (41, 42). Thus, Rac1 may function as a conduit for cellular signaling pathways, such as CaMKK $\beta$ -AMPK to control aspects of prostate cancer pathogenesis.

The enzymatic activity of CaMKK $\beta$  is regulated by Ca<sup>2+</sup>/calmodulin. Recently, augmented calcium intake has been correlated with increased prostate cancer incidence (43). Furthermore, calcium influx promotes the migration and metastasis of both prostate and breast cancers (44, 45). The data presented here may provide a mechanistic link between calcium uptake and cell migration. Our studies also show that overexpression of CaMKK $\beta$  alone was sufficient to increase AMPK activity and cellular migration. This suggests that the basal levels of calcium present in the prostate cancer cells were sufficient to result in CaMKK $\beta$  activation (Figs. 3 and 5). Hence, the observation that the levels of CaMKK $\beta$  alone dictate cellular processes (Fig. 3) underscores the importance of AR's regulation of CaMKK $\beta$  expression (Figs. 1 and 4).

Although various upstream signaling pathways have been shown to regulate the activity of CaMKK $\beta$ , to our knowledge, this is the first exhibited regulation of CaMKK $\beta$  expression by any signaling pathway. This strongly implicates a role for genomic androgen signaling in cellular migration. Other laboratories have suggested that androgens, through rapid nongenomic mechanisms, alter cytoskeletal reorganization and, in this manner, may impact migration (46, 47). In our hands, only prostate cancer cells expressing a wild-type AR, but not an AR containing a DNA-binding domain mutation that abrogated its transcriptional activity, could convey androgen-mediated cell migration (Supplementary Fig. S5). Additionally, androgens did not promote significant levels of cell migration a) within 6 hours of hormone treatment or b) in the presence of the transcriptional inhibitor actinomycin D (data not shown), indicating that androgen-mediated migration is not rapid and likely requires the genomic actions of AR. Thus, although androgens may increase cellular migration in part through nongenomic signaling, this work underscores the importance of the genomic actions of androgens in this process.

This study advocates the inhibition of the AR-CaMKK $\beta$ -AMPK pathway as a novel therapeutic approach for the treatment of prostate cancer. In particular, CaMKK $\beta$  represents a practical target for future drug development because of its restricted expression and the exhibited ability of small molecules to block its activity (ex. STO-609). Additionally, CaMKK $\beta$ -/- mice display no overt developmental

prostate abnormalities and do not exhibit fertility problems (data not shown). In subsequent studies, it will be interesting to cross these knockout animals with various prostate cancer mouse models to determine if CaMKK $\beta$  is required for their pathogenesis. Given what is currently known about CaMKK $\beta$  biology and considering the results of the studies reported here, we believe that in regards to prostate cancer therapeutics, an ideal inhibitor of this enzyme should exhibit selectivity for CaMKK $\beta$  over the related and more ubiquitous CaMKK $\alpha$  isoform and should not be able to cross the blood-brain barrier. This would isolate the actions of the drug and prevent it from interfering with CaMKK $\beta$ -regulated processes in the brain. Taken together, the data presented here indicate that a next-generation CaMKK $\beta$  antagonist displaying the above-described

pharmacological properties is likely to find utility as a treatment for prostate cancer.
